ABSTRACT

Quantifying the pace of ice-sheet growth is critical to understanding ice-age climate and dynamics. Here, we show that the diversion of the Hudson River (northeastern North America) late in the last glaciation phase (ca. 30 ka), which some previous studies have speculated was due to glacial isostatic adjustment (GIA), can be used to infer the timing of the Laurentide Ice Sheet's growth to its maximum extent. Landscapes in the vicinity of glaciated regions have likely responded to crustal deformation produced by ice-sheet growth and decay through river drainage reorganization, given that rates of uplift and subsidence are on the order of tens of meters per thousand years. We perform global, gravitationally self-consistent simulations of GIA and input the predicted crustal deformation field into a landscape evolution model. Our calculations indicate that the eastward diversion of the Hudson River at 30 ka is consistent with exceptionally rapid growth of the Laurentide Ice Sheet late in the glaciation phase, beginning at 50–35 ka.

INTRODUCTION

The Laurentide Ice Sheet reached its maximum extent over the last glacial cycle at the Last Glacial Maximum (LGM, 26 ka). Evidence of ice-sheet extent during the glaciation phase preceding the LGM is obscured by the subsequent retreat of the ice sheet, and is poorly preserved in the geological record (Clark et al., 1993; Dyke et al., 2002; Kleman et al., 2010). Geochronological constraints on ice-sheet history are difficult to obtain because much of the last ice age is beyond the age limit of radiocarbon dating, and the remaining geologic observations are characterized by sparse dates, using methods such as optical stimulated luminescence (OSL) or cosmogenic nuclides (Briner et al., 2006; Dalton et al., 2016). These limitations extend to other regions that were glaciated across the last ice-age cycle, and they pose a serious challenge to studies of glacial isostatic adjustment (GIA) prior to the LGM, in addition to hindering our understanding of the dynamics of ice-sheet growth. However, it should be possible to gather insight into ice-sheet histories by examining well-dated evidence of landscape evolution in unglaciated regions proximal to continental glaciation. GIA produces geographically variable crustal uplift and subsidence rates that reach many tens of meters per thousand years, a level sufficient to control river drainage patterns (Wallinga et al., 2004; Wickert et al., 2013; Wickert 2016) and delta morphology (Whitehouse et al., 2007).

The diversion of the Hudson River (northeastern North America) during the latest phase of Marine Isotope Stage 3 (MIS 3; 60–26 ka;

Siddall et al. 2008) is an example of landscape evolution that has been connected—albeit speculatively—to crustal deformation related to the growth of the Laurentide Ice Sheet and, in particular, the dynamics of its peripheral bulge (Knebel et al., 1979; Carey et al., 2005). The river was diverted eastward from its ancestral channel (dashed black line in Fig. 1), which has been dated to 40–30 ka using radiocarbon (¹⁴C) and amino acid racemization dating (Knebel et al., 1979; Sheridan et al., 2000; Carey et al., 2005) and mapped by seismic reflection surveys (Carey et al., 2005; Christensen et al., 2013; Santra et al., 2013). Though this river diversion at ca. 30 ka has been attributed to ice-age processes, this hypothesis has not been tested using process-based models of either GIA or landscape evolution.

Predicting how GIA modulates these river processes requires knowledge of the history of ice growth over North America prior to the LGM. Glacial geologists have mapped out terminal moraines tracing the maximum extent of the Laurentide Ice Sheet at the LGM: the Erie and Lake Champlain lobes entered Pennsylvania from the northwest and northeast, respectively, forming a triangular-shaped ice-free region between the two ice lobes (Braun 2004). Ice advanced to its maximum position in southern New England at 27–20 ka (Balco and Schaefer 2006); however, little evidence remains in New England of ice extent during the build-up phase (Corbett et al., 2017). Pre-LGM configurations of the Laurentide Ice Sheet have been constructed by Clark et al. (1993) on the basis of extensive stratigraphic records, and by Kleman et al. (2010) using a wide range of geomorphic evidence (eskers, ribbed moraines, ice-flow traces, and glacial striations). Nevertheless, given the uncertainties in chronology discussed above, it has not been possible to identify a spatially and temporally precise Laurentide Ice Sheet configuration during MIS 3. Recently, Dalton et al. (2016) inferred delayed glaciation of the eastern sector of the Laurentide Ice Sheet by dating non-glacial deposits in the region to 50–37 ka using OSL, uranium-thorium (U-Th), and ¹⁴C chronometers. They concluded that the Hudson Bay Lowlands was possibly ice-free from MIS 5a (100 ka) through mid-MIS 3 (ca. 40 ka).

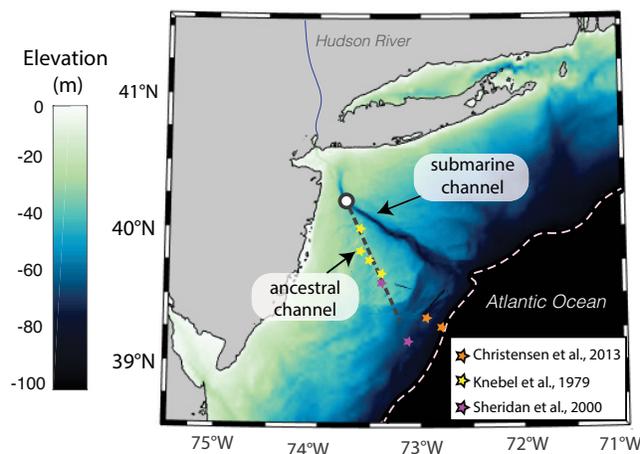

Figure 1. Present-day bathymetry on the Hudson shelf (northeastern North America). Colored stars indicate sites with dated deposits along the ancestral Hudson River, whose approximate path is shown by dashed black line. White circle indicates likely location of the river diversion. Dashed white line is the shoreline reconstruction at 26 ka based on calculations using ice model ICE-PC2. Thin, solid blue line is a schematic of the present-day Hudson river path.

In this study, we predict crustal deformation using GIA simulations based on a suite of possible ice-sheet histories and viscoelastic Earth structures, and use the predicted changes in topography to drive a landscape evolution model that allows river networks to evolve under spatially variable uplift. We use these results to explore the extent to which GIA may have controlled the diversion of the Hudson River.

GLACIAL ISOSTATIC ADJUSTMENT AND ICE HISTORIES

Ice-sheet growth and decay drive a complex pattern of sea-level (or equivalently, topographic) change. In our simulations, we performed sea-level calculations based on the theory and pseudo-spectral algorithm described by Kendall et al. (2005) with a spherical harmonic truncation at degree and order 256. In our primary GIA calculations, we adopt an Earth model with a lithospheric thickness of 96 km, and upper and lower mantle viscosities of 0.5×10^{21} Pa·s and 1.5×10^{22} Pa·s, respectively. This model is consistent with recent GIA studies involving data from the United States Atlantic coastal plain (Potter and Lambeck 2003; Creveling et al., 2017; Pico et al., 2017). In the GSA Data Repository¹, we consider the sensitivity of our results to these Earth model parameters.

We constructed a series of ice histories spanning the last glacial cycle that are used as input to the GIA simulations. In one case, we adopt the global ice history ICE-5G (Peltier and Fairbanks, 2006) across the last glacial cycle with two important modifications. The original Version 1.2 of the ICE-5G history assumes that prior to 26 ka, the ice sheet perimeter was fixed at the maximum perimeter. Our version adopts the same global mean sea-level variation as ICE-5G (Fig. 2A; dotted black line), but we make the common assumption that the geographic distribution of ice before 26 ka is the same as that afterwards, during the last deglaciation, for a given global ice volume (Raymo et al., 2011). Furthermore, we revise the ICE-5G LGM ice distribution to spatially resolve ice lobes described in the Dyke et al. (2002) reconstruction (Briner et al., 2006; Fig. DR1A in the Data Repository). We refer to this model as “modified ICE-5G”.

Many previous inferences of global mean sea level during the last glacial phase, and particularly during MIS 3, reconstruct higher sea levels (i.e., smaller global ice volume) than the ICE-5G history (e.g., Lambeck and Chappell, 2001; Pico et al., 2016; Creveling et al., 2017). Moreover, a recent GIA analysis demonstrated that anomalously high sea-level markers dated to 50–35 ka along the U.S. mid-Atlantic coast are reconciled

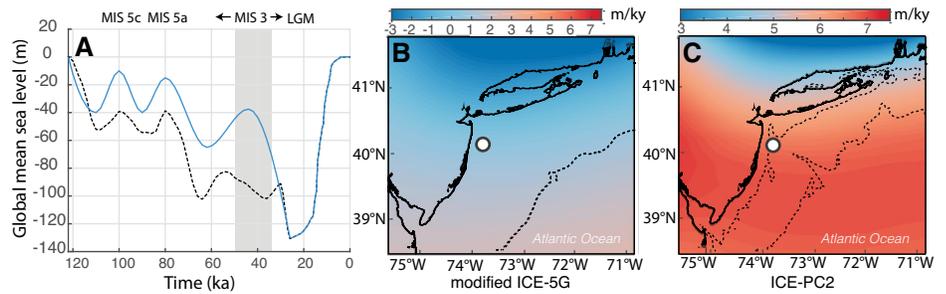

Figure 2. A: Global mean sea-level change predicted with the “modified ICE-5G” ice distribution history (dotted black) and the suite of ICE-PC histories (solid blue). Gray bar shows the interval from 50 to 35 ka, the time period to which the relative sea-level highstand is dated. The Last Glacial Maximum (LGM; 26 ka) is labeled. MIS—Marine Isotope Stage. **B,C:** Average rate of vertical displacement over the time interval 32–26 ka associated with glacial isostatic adjustment (GIA) in the region of interest computed using the (B) modified ICE-5G and (C) ICE-PC2 ice histories. Dotted-black lines denote the reconstructed shoreline locations at 32 and 26 ka. The lower sea-level shoreline represents 26 ka, and in panel B, the shorelines at 32 and 26 ka are nearly coincident. White circles mark the likely location of river diversion. Note the difference in color bars in panels B and C.

by adopting a significantly reduced eastern Laurentide Ice Sheet, and concluded that this sector underwent especially rapid growth from 44 to 26 ka (Pico et al., 2017). Motivated by these studies, as well as non-glacial deposits dated to mid-MIS 3 in eastern Laurentia (Dalton et al., 2016), we constructed an alternate ice history, which we denote as ICE-PC2. This ice history differs from “modified ICE-5G” by adopting a global mean sea-level history consistent with recent constraints on peak sea-level highstands across the glacial phase. In particular, these constraints suggest that global ice volumes reached above –20 m global mean sea level during both MIS 5a and 5c (ca. 100 ka and ca. 80 ka, respectively; Creveling et al., 2017) and that they tripled from 44 ka to 26 ka (Pico et al., 2016). The resulting global mean sea-level curve is shown in Figure 2A. In ICE-PC2, the eastern sector of the model Laurentide Ice Sheet is ice-free from 80 to 44 ka, and this region glaciates rapidly leading into the LGM from 44 ka to 26 ka (Fig. DR1D).

Finally, we constructed three other ice models that provide variations in the ICE-PC2 history to explore the sensitivity of river network evolution to the modeled ice history. These are denoted as ICE-PC, ICE-PC3, and ICE-PC4, and they are described in detail in the Data Repository.

RESULTS

Glacial-Isostatic Adjustment Predictions

To begin, we predicted the change in topography over the last glacial cycle using the “modified ICE-5G” model (black dotted line in Fig. 2A; Peltier and Fairbanks, 2006). The global mean sea-level curve associated with the modified ICE-5G history is characterized by ice volumes that reach near-LGM values by ca. 65 ka; i.e., prior to the beginning of MIS 3 (Fig. 2A). Because the solid Earth response to pre-65 ka ice-load variations has largely equilibrated by 30 ka, our modified ICE-5G–based calculation predicts

low rates of crustal deformation (~ 1 m/k.y.) and no pronounced regional west-to-east tilting from 32 ka to 26 ka (Fig. 2B). The observed eastward diversion of the Hudson River during this time period implies contemporaneous deformation in the region, with a decreasing gradient in crustal uplift rates from west to east, a pattern that is not predicted with the modified ICE-5G history.

We next performed GIA simulations adopting the ice history ICE-PC2, characterized by a rapid drop in global mean sea level from 44 to 26 ka (blue line in Fig. 2A). The average rate of change in topography predicted by this simulation from 32 to 26 ka is characterized by west-to-east tilting of the crust, which is particularly pronounced in the region bounding the predicted shorelines at 26 and 32 ka (dotted lines in Fig. 2C; Fig. DR2).

Landscape Response to Glacial-Isostatic Adjustment

Next, we explored how the landscape responds to the predicted GIA-induced deformation fields. Rivers respond through increased erosion or deposition to changes in channel slope at the shoreline, and numerous studies have focused on the response of coastal landscapes to globally uniform sea-level variations (Meijer 2002; Fagherazzi et al., 2004). Here, however, we focus on the response of rivers to GIA-induced crustal deformation. To highlight these effects, our landscape evolution simulations drive river network evolution only through fluvial processes in both transport- and detachment-limited rivers, and do not include coastal processes such as delta formation.

We performed simulations of landscape evolution using a generalized initial topography in the Hudson River region at the onset of the simulation (32 ka) because topography at this time was dissimilar to that of today. In particular, at ca. 13 ka, the Hudson River drained a catastrophic flood from pro-glacial Lake Iroquois, which led to up to 40 m of incision in the present-day channel, and the deposition of debris flows in the

surrounding regions of the shelf (Uchupi et al., 2001; Rayburn et al., 2005). As a consequence, maps of present-day elevation are a poor representation of the landscape at the time of the diversion of the Hudson River. Our model is instead initiated using a regional synthetic reconstruction of topography on a grid with a uniform spacing of 30 arc-seconds (~1 km; Fig. 3A; see the Data Repository) that is characterized by a north-south gradient similar to the general trend on the Hudson shelf (1 m/km); this yields paleo-Hudson River drainage that flows from north to south, consistent with paleoflow directions at ca. 30 ka recorded in the stratigraphic record (i.e., Carey et al., 2005; Fig. 1). Our goal in establishing the initial field of topography described above is to assess the general trends in the evolution of a north-to-south-flowing river in this location when subject to deformation due to GIA.

The location of river paths on the synthetic topography field is shown in Figure 3B, and the largest rivers (measured by drainage area $> 10^8$ m²) are shown in green. There are nine such rivers and ten “intermediate” ($> 5 \times 10^7$ m²) rivers (shown in blue in Fig. 3B). To explore whether GIA may have been responsible for the diversion of the Hudson River and whether this connection favors certain ice histories, we focus on the response of this synthetic river network to topographic changes predicted by each of the GIA simulations. Our measure of performance in this regard is the number of large and intermediate rivers diverted during the period 32 ka to 26 ka.

To quantify river network responses to GIA-induced crustal deformation, we adopt the Channel-Hillslope Integrated Landscape Development (CHILD) landscape evolution model, which includes parameterizations for both detachment-limited and transport-limited processes (Tucker et al. 2001; Tucker, 2010), both of which may influence river evolution in the study region. We drove CHILD simulations by applying time-variable uplift rates drawn from the GIA predictions from 32 to 26 ka (Fig. DR2) to the initial topography, and computed the responses in the resulting river network. The parameter values adopted for these simulations are listed in Table DR1, and we review the fluvial and hillslope processes applied in CHILD and describe additional simulations that vary parameter choices in the Data Repository. These sensitivity tests revealed that the number of modeled river diversions is relatively insensitive to the relative dominance of detachment-limited or transport-limited conditions.

Driving the landscape evolution model with the vertical displacement field produced by ice history ICE-PC2 (Fig. 2C), and adopting the erodibility parameters described in the Data Repository, predicts that all nine large rivers and six intermediate rivers are diverted eastward by 6 k.y. after the onset of the simulation at 32 ka (a total of 19 sites of eastward diversion and

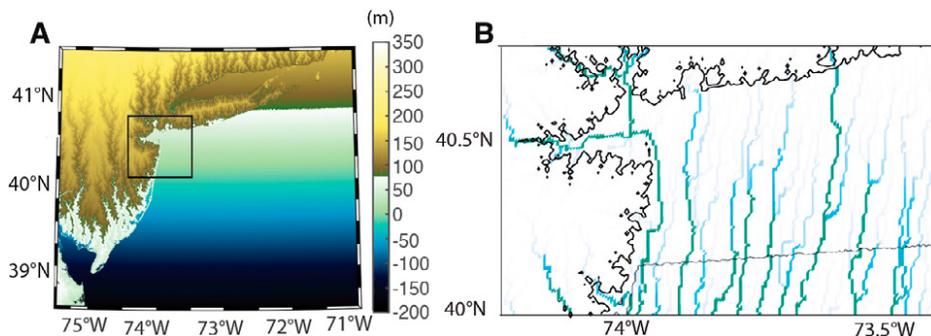

Figure 3. A: Regional reconstruction of topography used to initialize the landscape evolution simulations at 32 ka. Black box outlines the region used in landscape evolution simulations. B: River drainage patterns within the boxed region of panel A, illustrating the location of nine large rivers, in green.

2 sites of westward diversion along 17 rivers; gray circles in Fig. 4B). This trend is consistent with the eastward diversion of the Hudson River preserved in the geological record. In contrast, only six large rivers and one intermediate river are diverted eastward when the simulation is driven by deformation associated with the modified ICE-5G simulation using the same Earth model and erodibility parameters (a total of nine sites of eastward diversion and one site of westward diversion along 16 rivers; gray circles in Fig. 4A).

DISCUSSION

Analogous predictions for additional ice histories and Earth models are shown in Figures DR3–DR6. We note that the predicted west-to-east pattern of deformation does not reflect the broader geometry of the Laurentide Ice Sheet peripheral bulge, which spans the greater part of the United States, but is due to a superimposed, smaller-scale peripheral bulge formed by the Erie ice lobe (Fig. DR1A; Dyke et al., 2002). The tilting caused by the late and rapid growth of the Laurentide Ice Sheet and its associated ice lobes could have been sufficient to have affected other rivers along the U.S. east coast, including the Delaware River, a connection that warrants further study.

CONCLUSIONS

Previous studies have speculated that the eastward diversion of the Hudson River at ca. 30 ka was driven by changes in topography associated with ongoing GIA (e.g., Knebel et al., 1979). Our modeling of both GIA and the associated river network evolution provides strong quantitative support for this hypothesis. An eastward diversion requires that the GIA field introduce a west-to-east tilting of topography. Our simulations indicate that this tilting would have been a natural consequence of a rapid, late growth of the eastern Laurentide Ice Sheet before the LGM. These simulations suggest that the Hudson River likely was diverted during the sea-level fall as the shoreline passed through the region of maximum

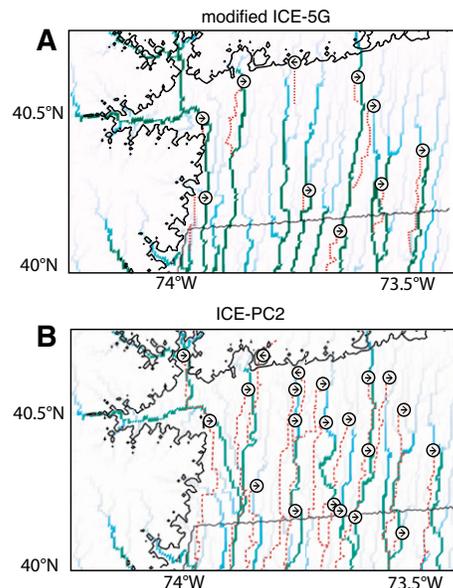

Figure 4. River drainage pattern computed using Channel-Hillslope Integrated Landscape Development (CHILD) model after the initial topography in Figure 3A is perturbed by regional glacial isostatic adjustment (GIA) predicted using the ice models: (A) modified ICE-5G (Fig. 2B), and (B) ICE-PC2 (Fig. 2C). Darker colors are used to highlight larger rivers. Eastward and westward diversions are labeled by arrows. Dashed red lines show original paths of these rivers prior to the imposition of the GIA deformation field (Fig. 3B). Thin black line represents shoreline position (as in Figs. 3A and B) adopted in the landscape evolution model at the start of the simulation.

west-east tilting from 32 to 26 ka. Our simulations ignore shallow coastal processes, including backwater effects and autogenic avulsions; incorporating these effects may increase the likelihood of diversions.

Our results demonstrate that solid-Earth deformation over Pleistocene glacial cycles can be an important influence on landscape evolution in regions without glacial cover, particularly at the periphery of former ice sheets, where information about past river evolution can refine estimates of glaciation rates.

The Darker Side of John Wesley Powell

Like other early American geologists, the man who explored the Colorado River did anthropologic research that presupposed the racial inferiority of Native Americans

By Tamara Pico on September 9, 2019

The year 2019 marks the 150th anniversary of the 1869 Powell Expedition, the first U.S. government-sponsored expedition through the Colorado River into the Grand Canyon. In honor of the famous expedition, the United States Geologic Survey sponsored the “Sesquicentennial Colorado River Exploring Expedition,” retracing the path of Powell’s boats and engaging the public along the way about this historic geologic expedition.

How we recount science history events is important because the way we tell these stories relays values and cultural norms to the next generation of scientists. Early geologists are often discussed in terms of intellectual contributions, strong personalities or heated debates. But what was the historical context and the motivation behind their work? This context is inseparable from scientific contributions to geoscience, and contributes to the culture within the geology community today.

John Wesley Powell (1834–1902) is a foundational figure in American geology, and is extolled as an exceptional scientist, explorer and environmentalist. One hundred and fifty years later, Powell is well-known for leading an expedition rafting down the Colorado River into the Grand Canyon in 1869. Powell’s legacy in the geology community is that of an explorer: a relentless adventurer who fearlessly blazed through the unknown.

Though Powell is regarded as a hero in geology, he did more than map out rocks and landscapes. He also conducted ethnographic work on Native American tribes with the goal of “civilizing” Native Americans. As the director of the USGS and head of the Bureau of Ethnology at the Smithsonian, Powell played a powerful role in government decisions around Native American affairs. The 150th anniversary of this renowned expedition marks an opportunity to revisit the legacy of early American geologists such as John Wesley Powell in light of their social and political impact.

GEOLOGY AND WESTWARD EXPANSION

In the U.S., the discipline of geology developed in parallel to westward expansion. Overlap between military imperialist ventures and geologic expeditions was quite clear, as the U.S. government was invested in mapping out these territories, identifying valuable resources and removing indigenous people from these lands. In the 1860s several expeditions were commissioned by the U.S. Secretary of the Interior with the goal of detailing the topography,

geology and natural history of the recently annexed U.S. western territories.

National recognition of geology as a discipline was tied to government sponsorship through the establishment of the U.S. Geological Survey (USGS) in 1879. From 1867 to 1876, during the transition to an officially recognized USGS, major expeditions including the Hayden survey in the Yellowstone region, the Wheeler survey west of the 100th meridian, the King survey in eastern California and Wyoming, and the Powell survey in the Rocky Mountain region (including the Colorado River) served to examine the potential resources in these territories. These survey leaders were formative to the history of geology, and their proposed geologic interpretations were written alongside recommendations for resource development and Native American removal.

MAPPING AND POWER

Powell published the first report of his explorations in 1870, in a travel book entitled *New Tracks in North America*, which contained a compilation of stories about adventures in the West. Also included in this anthology were the adventures of another white man who rafted through the Grand Canyon on the Colorado River several years before (admittedly in poorer conditions than Powell, as he was half-consciously pummeled by the river until rescued by a group of Native Americans). The British editor, William Bell, explains in the preface that these explorations are especially necessary to produce knowledge about western North

America, because this country contains “cradles for nations which are destined to spring from our own hardy and prolific stock.”

This language was common in 19th century research in geology and geography, which connected physical landscapes and climates to human race characteristics. Scientists argued that certain topographies and climates produced humans who could not rise from a “grade of savagery”, and were destined to be developed by “civilized races,” even suggesting that North America was especially well-suited for the institution of slavery.

Despite Powell’s later interest in ethnographic studies, during his first expedition down the Colorado in 1869, he made remarkably few notes in his diary about the presence of ruins or recent Native American camps. In fact, over 250 archeological sites have been found in the region of the 1869 expedition, 37 of them directly on the route that Powell reportedly took. Other members of the expedition made more extensive notes than Powell about the presence of other humans on their path, noting they “found the camp of an Indian today with meat bones that had been picked within two months.” Invariably, Powell skewed the narrative of his expedition to appear more uncharted than it truly was.

Because the expedition had been justified on the basis of mapping the course of the river and its geology, Powell similarly downplayed topographic knowledge held by Native American communities. Though he underlined that their intense familiarity with the landscape was crucial to the expedition, putting his ability to remember topographic features “to shame,” he emphasized that his knowledge (presumably using and producing Western maps) captured the most important aspects, which he deemed essential in describing the large-scale features of a country. Indeed, mapmaking is a “form of knowledge and a form of power” which was used as an intellectual weapon of imperialism to control space and its inhabitants.

Powell employed this knowledge of topography as a resource for power. In *Exploration of the Canyons of the Colorado*, Powell explained to Native Americans that he was not interested in trade, but instead,

"I tell them that all the great and good white men are anxious to know very many things, that they spend much time in learning, and that the greatest man is he who knows the most; that the white men want to know all about the mountains and the valleys, the rivers and the canyons."

Powell published extensive anthropological studies on native people and language, including the Ute people inhabiting these canyon lands, seeking to provide evidence for the inferior status of Native American culture and expounding a stepping-stone between "barbarism" and "civilization." In a report to the U.S. government entitled "On the condition of Ute Indians of Utah," Powell proposed:

"... next to teaching them to work, the most important thing is to teach them the English language. Into their own language there is woven so much mythology and sorcery that ... the ideas and thoughts of civilized life cannot be communicated to them in their own tongues."

Advocating for government funding to be used to "civilize" Native American populations, Powell pushed for the teaching of English, Christianity and Western methods of farming and manufacture. The study of ethnology was used as a tool for scientists to demarcate social categories in order to justify government-sponsored programs that exploited newly adopted land and its inhabitants. Although today we view the field of ethnology as separate from geology, 19th century scientists such as Powell likely viewed this work together, and these studies were published side by side in reports to the public and the U.S government.

A COMPLEX LEGACY

ADVERTISEMENT

Origin stories, such as Powell's expedition to the Grand Canyon 150 years ago, are told in introductory Earth science classes and are instrumental in setting cultural norms in geology. This culture can powerfully determine who feels a sense of belonging in a classroom or in a career as a geologist. Powell, among other early American geologists, furthered anthropologic research invested in the racial inferiority of Native Americans, and was motivated by military imperialism.

This history makes it challenging to cleanly separate the story of a geology hero from the complex motives underlying the explorations that built the foundations of Earth science. A century and a half later, as the talented pool of geoscientists becomes increasingly diverse, we can revisit how we tell the legacy of early American geologists. Their stories, which reinforce values in the discipline, merit a fuller understanding of the broader social landscape that shaped the course of research by U.S geologists.

By mapping topography and possessing knowledge of landscapes, Powell can make the Colorado River legible to the U.S. government as capital to be owned and exploited.
